Outline

Overview of symmetric cryptography

Modes for encryption

Stream encryption with block ciphers

Provable security of modes

Authentication with block ciphers

Overview of symmetric cryptography

Symmetric cryptography operations

- Basic operations
 - encryption
 - MAC computation
 - authenticated encryption (including sessions)
- ▶ Require a key shared between sender and receiver
- Auxiliary operations
 - cryptographic hashing
 - deterministic random bit generation (DRBG)
 - . . .
- ▶ Not really symmetric crypto but often categorized as such
 - true random generators
 - secret sharing for key management

Need for secret keys in symmetric cryptography

- Symmetric stands for
 - same key for encryption and decryption
 - same key for MAC generation and verification
- ► Basic operations achieve following:
 - reduce problem of securing (big) data
 - to problem of securing (small) keys
- ► A secure solution requires secrecy of keys
 - key generation requires qualitative random generator
 - key transfer between entities requires other keys
 - modules performing crypto shall not leak keys
 - many potential weaknesses

Limit to security: exhaustive key search

- Exhaustive key search
 - given some input/output $(M = 1) \dots$
 - trying all different keys (N)
- ► Single-target attack: one particular *k*-bit key *K*
 - success prob. after N trials: $N2^{-k}$,
 - expected effort $N \approx 2^{k-1}$
 - (implicit) security claim: this should be best attack
 - so a k-bit key limits security strength to k bits
- ► Multi-target attack:
 - attacker is happy if she finds one key out of n keys K_i
 - relevant in many cases
 - e.g., if keys K_i are on badges giving access to a building

Limit to security: multi-target exhaustive key search

- ► Multi-target attack setting example
 - attacker knows $Z_i = SC_{K_i}(D = 1, \ell)$ for n keys K_i
- Attack:
 - guess K' and compute $Z' = SC_{K'}(D = 1, \ell)$
 - until $Z' \in \{Z_i\}$: success
 - success probability per trial: $\geq n2^{-k}$
 - expected effort $N \approx 2^k/(n+1)$,
- ▶ Security erosion: 128-bit key offers much less than 128-bit strength
 - Security strength decreases to $k log_2(n)$
- ▶ this can be prevented by including globally unique nonce
 - e.g., key ID_i plus message counter $Nr: Z_i = SC_{K_i}(ID_i||Nr, \ell)$
 - or, random string R of sufficient length $Z_i = SC_{K_i}(R, \ell)$

Security erosion

Security strength is smaller than key if multi-target attacks are possible

Modes for encryption

Block cipher modes for encryption

- ▶ DES can encipher 8-byte messages, AES 16-byte messages
 - what about longer and shorter messages?
 - two approaches: block encryption and stream encryption
- ▶ Block encryption modes
 - split the message in blocks
 - after padding last incomplete block if needed
 - apply permutation B_K to blocks in some way
- Stream encryption modes
 - build a stream cipher with a block cipher as updating function
 F or output function f

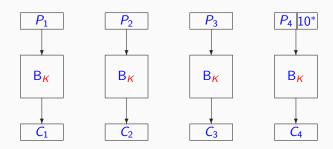

Block encryption modes

- ► Electronic Code Book (ECB) mode
 - we consider only 16-byte messages
 - longer messages are split in 16-byte blocks
 - shorter messages padded to 16 bytes
 - same for last incomplete block
- ► Cipher Block Chaining (CBC) mode
 - ECB randomized with what's available
 - requires also split in 16-byte blocks and padding
- ▶ Due to padding, cryptogram is longer than message

Intermezzo: padding

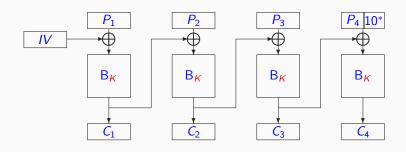

- ► Simplest padding: append zeroes
 - up to length multiple of block length (e.g. 16 bytes)
 - shortest possible padding
 - as such not usable for our purposes
- ▶ Decryption of cryptogram gives padded message
- ► Recovering message requires removing padding
 - send along message or padding length with cryptogram, or
 - impose padding is injective (or reversible)
- ▶ Simplest reversible padding: a single 1 and then zeroes
 - extends message in all cases
 - turns 16-byte message into 32-byte string
- ► Padding with exotic requirements
 - random-length padding: to hide message length
 - random padding: to add entropy
- ▶ Badly designed padding is often source of security problems

Electronic CodeBook Mode (ECB)

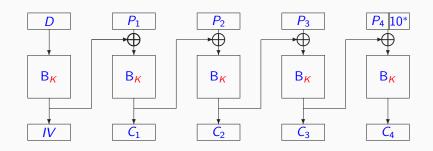

- Advantages
 - simple
 - parallelizable
- ightharpoonup Limitation: equal plaintext blocks ightarrow equal ciphertext blocks:
 - likely to happen in low-entropy messages
 - problem in padded last block, that can be a single byte

Cipher Block Chaining mode (CBC)

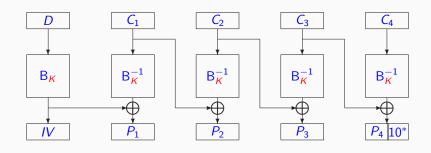

- ▶ ECB with plaintext block randomized by previous ciphertext block
- ► First plaintext block randomized with **random** Initial Value (*IV*)
- Solves leakage in ECB (partially):
 - equal plaintext blocks do not lead to equal ciphertext blocks
 - requires randomly generating and transferring IV

Cipher Block Chaining mode (cont'd)

- ▶ Replacing IV randomness by D nonce requirement: $IV = B_K(D)$
- CBC properties
 - encryption strictly serial
 - IV or diversifier D must be managed and transferred

Cipher Block Chaining decryption

- ▶ Decryption can be done in parallel
- ▶ Bottom line
 - we still need a nonce despite doing block encryption
 - but ok, nonce re-use leaks less information

Stream encryption with block ciphers

Stream encryption with a block cipher

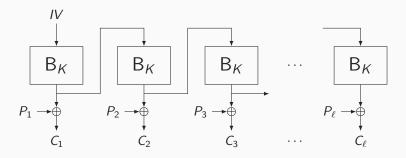

- ▶ Remember structure of iterative stream ciphers:
 - state update function $s^t = F(s^{t-1})$
 - output function $z_t = f(s^t)$
- ▶ Stream encryption modes of a block cipher:
 - use a block cipher for F or f

Output FeedBack mode (OFB)

- $ightharpoonup F = \mathsf{B}_{\kappa}$, so $s_t \leftarrow \mathsf{B}_{\kappa}(s_{t-1})$
- ▶ f is identity: $z_t \leftarrow s^t$
- ▶ Initialization: storage of K and $s_0 \leftarrow D$ (often called IV)
- ▶ Properties:
 - strictly serial
 - cycle lengths not known in advance
 - \bullet no need for $\mathsf{B}_{\mathsf{K}}^{-1}$ (valid for all stream encryption)

OFB encryption presented in the classical way

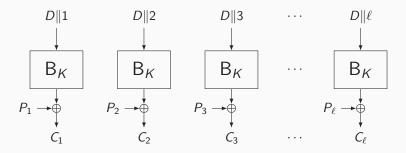

Note: the diversifier is often denoted as IV

Counter mode

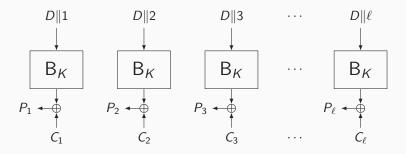

- ▶ F: interpret s^t as integer and add 1: $s^t = s^{t-1} + 1$
- $ightharpoonup f = \mathsf{B}_{K}$, so $z_{t} = \mathsf{B}_{K}(s^{t})$
- ▶ Initialization: storage of K and $s_0 \leftarrow D \| 0$ (often called IV)
- Properties
 - fully parallelizable
 - $\ell = |Z|$ for given D limited to $2^{b-|D|}$ blocks
 - no risk of short cycles

Counter mode encryption presented in the usual way

Counter mode decryption presented in the usual way

Encryption modes: overview

	ECB	CBC	OFB	Counter
parallel encryption	у	n	n	у
parallel decryption	У	У	n	у
random access	У	У	n	У
B^{-1} -free	n	n	У	у
padding-free	n	n	У	у
bit errors $C \rightarrow P$ limited	n	n	У	у
nonce-violation tolerant	n. a.	у	n	n

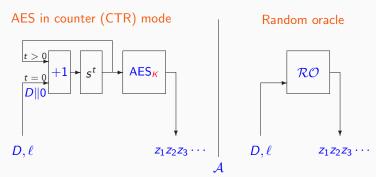

Legend:

- ▶ random access: fast decryption of bits anywhere in the message
- ▶ bit errors limited: bitflips in C do not spread out in P

Provable security of modes

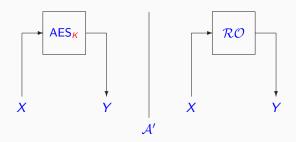

Provable security of a counter mode scheme

(calls to internals symbolizing computational complexity omitted)

- Security of concrete scheme
 - advantage in distinguishing real and ideal world
 - denoted as $Adv_{\mathcal{A}}(\mathsf{CTR}_{\mathsf{AES}_{\kappa}}, \mathcal{RO})$
- ► Hard to analyze as such . . .
 - we break this into simpler problems with some techniques
 - this set of techniques form the discipline of *provable security*

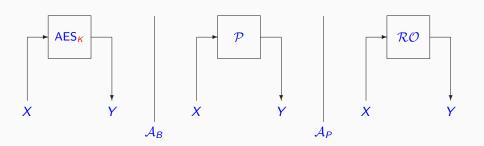

Provable security: simulation

- lacktriangle We replace ${\cal A}$ by an adversary ${\cal A}'$ that has more power
- \blacktriangleright A can be simulated by \mathcal{A}'
 - ullet response to any query sent by ${\mathcal A}$ can be obtained by ${\mathcal A}'$
 - ullet being asked to distinguish, \mathcal{A}' can just ask \mathcal{A}
 - ...as she could do it herself
 - advantage of \mathcal{A}' cannot be smaller than that of \mathcal{A} :

$$\mathrm{Adv}_{\mathcal{A}}(\mathsf{CTR}_{\mathsf{AES}_{\pmb{\kappa}}},\mathcal{RO}) \leq \mathrm{Adv}_{\mathcal{A}'}(\mathsf{AES}_{\pmb{\kappa}},\mathcal{RO})$$

Provable security: triangle inequality

- \blacktriangleright We add a step in between, here a random permutation ${\cal P}$
 - Adversary A_B distinguishes between AES_K and P
 - Adversary \mathcal{A}_{P} distinguishes between \mathcal{P} and \mathcal{RO}
- ► Triangle inequality:

$$\mathrm{Adv}_{\mathcal{A}'}(\mathsf{AES}_{\mathbf{K}},\mathcal{RO}) \leq \mathrm{Adv}_{\mathcal{A}_{\mathcal{B}}}(\mathsf{AES}_{\mathbf{K}},\mathcal{P}) + \mathrm{Adv}_{\mathcal{A}_{\mathcal{P}}}(\mathcal{P},\mathcal{RO})$$

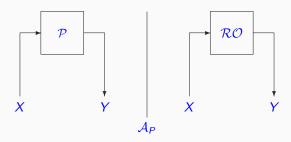

Separation of primitive cryptanalysis and mode security proofs

$$\operatorname{Adv}_{\mathcal{A}'}(\operatorname{\mathsf{AES}}_{\kappa}, \mathcal{RO}) \leq \operatorname{Adv}_{\mathcal{A}_{\mathcal{B}}}(\operatorname{\mathsf{AES}}_{\kappa}, \mathcal{P}) + \operatorname{Adv}_{\mathcal{A}_{\mathcal{P}}}(\mathcal{P}, \mathcal{RO})$$

The advantage has two components:

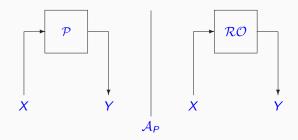

- ► Advantage of the primitive
 - here: PRP security of AES
 - domain of cryptanalysis
 - cannot be proven, only assumed, claimed and challenged
- ▶ Advantage of the mode assuming ideal component
 - here: (CTR mode of a) random permutation P
 - domain of provable security
 - bounds can be proven using probability theory

Provable security of counter mode as such

- ightharpoonup Difference in behaviour between \mathcal{P} and \mathcal{RO}
 - P returns random non-colliding responses
 - RO returns uniform random responses
- ▶ This implies that A_P can distinguish P from RO if and only if
 - she is speaking to RO AND
 - *RO* returns colliding outputs

Provable security of counter mode as such (cont'd)

 \blacktriangleright After queries, \mathcal{A}_P returns 1 if there was a collision and 0 otherwise

$$Adv_{\mathcal{A}_{\mathcal{P}}}(\mathcal{P},\mathcal{RO}) = |\Pr(\mathcal{A}_{\mathcal{P}} = 1 \mid \mathcal{RO}) - \Pr(\mathcal{A}_{\mathcal{P}} = 1 \mid \mathcal{P})| = \Pr(\mathsf{coll.} \mid \mathcal{RO})$$

▶ We have

$$Pr(coll. \mid \mathcal{RO}) \approx {M \choose 2} 2^{-128} \approx M^2 2^{-129}$$

▶ Advantage gets close to 1 when $M \approx 2^{64}$: the birthday bound

Authentication with block ciphers

Message authentication code (MAC) functions

- ► MAC: cryptographic checksum
 - input: key K and arbitrary-length message m
 - output: tag (aka MAC) T with some length ℓ
- ► Applications:
 - message authentication: append tag to message
 - entity authentication: compute tag over challenge

We can formally write: $T \leftarrow \mathsf{MAC}_{\kappa}(m)$

Two types of MAC function (online) queries:

- ▶ Generation: give m and get $T \leftarrow MAC_K(m)$
- ▶ Verification: give (m, T) and get 1 if $T = MAC_K(m)$ and else 0

Security goal

MAC forgery

Generating a couple (m, T) such that tag verification returns 1 without knowing K and without querying tag generation with m

- ► Security goal of a MAC function: forgery should be hard
- ▶ How hard?
- ▶ Ideal MAC function:
 - tags fully unpredictable when keyed with unknown K
 - ...except that same message returns same tag
 - This is like a random oracle with ℓ-bit output!
- ▶ Success probability of forgery after M attempts for \mathcal{RO} : $M2^{-\ell}$
- ▶ Just trying (m, T) with same m and different T until we hit the right tag

So we want our keyed MAC function to be like a random oracle

Pseudorandom function (PRF) security of a MAC function MAC() is PRF-secure if $MAC_K(m)$ is hard to distinguish from \mathcal{RO}

Implications of PRF-security bound of a MAC function

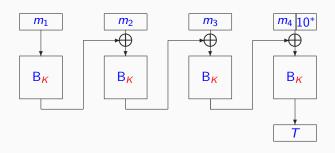

PRF-advantage of a MAC function

$$\mathrm{Adv}_{\mathcal{A}}(\mathsf{MAC}_{\boldsymbol{\kappa}},\mathcal{RO}) = |\operatorname{\mathsf{Pr}}(\mathcal{A} = 1 \mid \mathsf{MAC}_{\boldsymbol{\kappa}}) - \operatorname{\mathsf{Pr}}(\mathcal{A} = 1 \mid \mathcal{RO})|$$

A (claimed) advantage $\mathrm{Adv}_{\mathcal{A}}(\mathsf{MAC}_{\mathcal{K}},\mathcal{RO}) \leq \epsilon(\mathcal{M},\mathcal{N})$ says something about the success probability of forgery

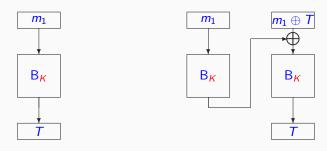

- \triangleright Recipe for distinguishing adversary \mathcal{A} based on forging ability:
 - (1) Spend resources N and M on trying to generate forgery
 - (2) If it works, return 1, else return 0
- ▶ $Pr(A = 1 \mid RO) = Pr(forgery success for RO) \leq M2^{-\ell}$
- ▶ $Pr(A = 1 \mid MAC_{K}) = Pr(forgery success for MAC_{K})$
- ▶ Due to the claim: $Pr(\text{forgery success for MAC}_{\kappa}) \leq M2^{-\ell} + \epsilon(M, N)$

Cipher Block Chaining MAC mode (CBC-MAC)

- ▶ Observation: in CBC ciphertext block C_i depends on m_0 to m_i
- ► Idea:
 - apply CBC encryption with zero IV to (padded) message
 - take tag equal to last ciphertext block
 - throw away other blocks (essential for security)
- ▶ This is the basis for most block-cipher based MAC functions

CBC-MAC weakness: length extension

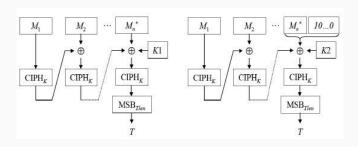

- \blacktriangleright Distinguishing from random oracle \mathcal{RO} in two queries:
 - query m_1 returns $T = \mathsf{B}_{\mathsf{K}}(m_1)$
 - query $m_1 \| m_2$ with $m_2 = m_1 \oplus T$ returns

$$\mathsf{B}_{\boldsymbol{\mathsf{K}}}(m_2 \oplus \mathsf{B}_{\boldsymbol{\mathsf{K}}}(m_1)) = \mathsf{B}_{\boldsymbol{\mathsf{K}}}(m_1 \oplus T \oplus \mathsf{B}_{\boldsymbol{\mathsf{K}}}(m_1)) = \mathsf{B}_{\boldsymbol{\mathsf{K}}}(m_1) = T$$

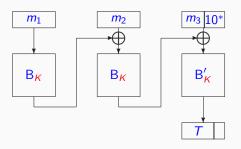

- ▶ A random oracle will give two completely unrelated tags
- Note: attack ignores padding, but this can be dealt with
- truncating the tag T helps (somewhat) against this attack

A fix of CBC-MAC: C-MAC [NIST SP 800-38B]

- ► Trick: avoid length-extension problem by *doing something different* at the end: finalization
- \blacktriangleright Here: addition of a *subkey* before last application of B_{K}
- lacktriangleright Advantage in distinguishing this from \mathcal{RO} assuming random \mathcal{P}
 - birthday bound $M^22^{-(b+1)}$ due to inner collisions
 - see next slide

Security of CBC-MAC based modes: birthday bound

- ► Consider CBC-MAC with *finalization* B'_K, e.g., C-MAC
- ▶ Distinguishing this from a \mathcal{RO} :
 - query for many 3-block inputs $m^{(i)}$ of the form $m_1m_2m_3$
 - m_1 and m_2 different in each query, m_3 always the same
- ▶ Collision for $i \neq j$ at input of B'_{K} gives colliding tags
 - detect internal collision by tag collision plus some check queries
 - then $\forall m'$: $m^{(i)} || m'$ gives same tag as $m^{(j)} || m'$
- ▶ RO has no internal collisions

Summary

Summary

- ▶ Block ciphers are versatile:
 - block encryption modes: e.g., ECB and CBC
 - stream encryption modes: e.g., OFB and counter
 - MAC computation modes: e.g., CBC-MAC and C-MAC
- ▶ Inverse permutation only used in block encryption modes
- Security analysis of cryptographic schemes splits in two parts
 - primitives must be cryptanalyzed, no security proofs
 - modes can be proven secure with probability theory
- Most modes only secure up to birthday bound
 - processing 2^{b/2} blocks with same key will show non-ideal behaviour
